Abstract: Lipid composition of *Heterotis niloticus*, *Brycenus nurse*, *Gnathonemus cyprinoides* and *Sarotherodon galilaeus*, which vary in scale thickness, were studied. *Heterotis niloticus* (very thick scales) had the lowest lipid content (13%), while *G. cyprinoides* (light scales) had the highest lipid content (26%). The common neutral lipids were cholesterol, free fatty acids and cholesterol esters, while diphosphatidyl glycerol, phosphatidyl glycerol and phosphatidyl ethanolamine were the most predominant phospholipids.

Key words: Pisces, scales, lipids, neutral and phospholipids.

Fish lipids vary considerably in their fatty acid composition and fish oil has a high percentage of unsaturated fatty acids. This makes fish oil more reactive than oil from most land animals and plants (Clucas and Ward 1996). Most animals and some fish are known to store fat under the skin to provide protection, thermal insulation against heat loss and to store energy when dietary requirements are not met. Some fishes store fat in the liver while others store fat in the peritoneum (Deuel 1957, Clucas and Ward 1996).

Scales are an outstanding feature of fish skin. They vary in types and shapes. Structurally there are two types of fish scales, placoid and non-placoid. Bony-rigde scales are typically thin, translucent and non-placoid, lacking both dense enamloid and dentinal layers. Scales are either cycloid or ctenoid and they characterize living species of bony fishes (Osteichthyes) (Lagle et al. 1977).

The main features which affect the quantity and quality of the fish oil are fish species, food, spawning cycle, water and temperature (Deuel 1961, Huss 1988, Clucas and Ward 1996). Lipids provide a concentrated energy source. In bonefish *Albula* sp. larvae, lipid catabolism accounted for about 80% of the total energy production during metamorphosis (Padron et al. 1996). Murray and Burt (1969) showed differences in the lipid composition of marine fishes; in the blue whiting (*Micromesistius poutassou*) the lipid content was 1% to 3.8%, in the cod (*Gadus morhua*) the lipid content ranged from 0.1 to 0.9%, in the salmon (*Salmo trutta*) the lipid content was 1.2 to 10.8% and in the white herring (*Clupea harengus*) the lipid content ranged from 0.4 to 22%. *Clarias gariepinus* adults had a lipid content of 1.32%, while fingerlings had a lipid content of 1.04% (Ayinla 1993). Omotosho and Olu (1995) showed that lipid content decreased with frozen storage in *Tilapia zilli*, *Clarias lazera*, *Channa obscura* and *Synodontis schall*. Soriguer et al. (1996) classified fish into low fat and fatty, and stated that the classification depended on the time of the year the fish was caught; for example, the horse-mackerel
Scomber scombrus in spring had the same fat content as the sole Soles vulgaris which is generally considered as a low fat fish.

Heterotis niloticus, Bryucus nurse, Gnathonemus cyprinoides and Sarotherodon galilaeus are commercially important to freshwater fisheries in Nigeria, and they constitute a major part of the landing and sources of animal protein. There is paucity of knowledge on the lipid composition of these freshwater fishes. This work aims at elucidating the lipid composition in these fishes and the relationship between scales and lipid composition in these fish species.

MATERIALS AND METHODS

Fish used in this study were collected from a small man-made lake in Ilorin Nigeria using gill nets. They were selected based on the external morphology. They are categorized into thick, moderately thick and light scales (Table 1).

Two size groups were used: juvenile and adult based on standard body length. Standard laboratory measurements were taken: total weight, total length, standard length. The fish were dried in the oven at 60°C to a constant weight. The total lipid was determined using the soxhlet extraction method of A.O.A.C. (Anonymous 1980). The composition of the lipid was determined using thin layer chromatography (TLC) according to Wilson and Walker (1996). Neutral lipids were separated using petroleum ether, diethyl ether, and acetic acid, in a proportion 80/20 v/v/v. The phospholipids were resolved with the solvent system chloroform, methanol and water, in a proportion of 62/25/4 v/v/v.

RESULTS

The various size groups of the fishes studied are shown in Table 2. There was variation in the lipid content of B. nurse, H. niloticus, G. cyprinoides and S. galilaeus as indicated in Table 3. The lowest percentages of lipids were obtained in both juvenile and adult H. niloticus, which had very thick scales, while the highest lipid content was obtained in G. cyprinoides with light scales, and it was closely followed by B. nurse and S. galilaeus with moderate scales.

The neutral lipid composition showed that free fatty acids and cholesrol were more abundant (Table 4). Cholesterol and free fatty acids were more abundant in the neutral lipids in both juveniles and adults while the phospholipids were more abundant in adults than in juveniles. The phospholipid composition is shown in Table 5. Diphosphatidyl glycerol was the most abundant, followed by phosphatidyl glycerol and phosphatidyl ethanolamine which were mostly observed in juveniles. Phosphatidyl choline was detected only in H. niloticus.

DISCUSSION

Deuel (1961, Clucas and Ward 1996) showed that factors such as nutrition and fish species tend to affect the oil content of the fish. Deuel (1961) suggested that fat depot was entirely composed of neutral lipids, while phospholipids were more abundant in organs than in muscle. In the present work only the

muscle were examined. Padron et al. (1996) demonstrated in Albula sp. that neutral lipid constituted about 64.2%, while polar lipid constituted 35.8%. They further showed that triacylglycerol, the principal neutral lipid of all metamorphic stages, accounted for about half the decrease of the total lipid; in the present study, triacylglycerol was present in the juvenile of almost all the fishes except H. niloticus.

Padron et al. (1996) demonstrated that in Albula sp. the level of phosphatidyl ethanolamine in early larvae decreased by more than 50% during metamorphosis. Phosphatidylcholine increased in adult of Albula sp. The lipid composition of the fish species in this study showed much variation which can be attributed to physiological changes in the body of the fish and other factors in the environment.

**RESUMEN**

Se estudió la composición de lípidos de Heterotis niloticus, Brycenus nurse, Gnathonemus cyprinoides y Sarotherodon galilaeus, los cuales varían en el grosor de las escamas. Heterotis niloticus (escamas muy gruesas) tuvo el contenido de lípidos más bajo (13%), mientras que **G. cyprinoides** tuvo el más alto (26%). Los lípidos neutrales comunes fueron el colesterol, los ácidos grasos libres y los ésteres del colesterol, mientras que el dífosfatidil glicerol, el fosfatidil glicerol y la fosfatidil etanolamina fueron los fosfolípidos más predominantes.
