ABSTRACT

Introduction: The “restingas” (coast vegetation) can serve as a species corridor in ecotonal environments due to the particulars regarding the composition of the flora. The studies covering the entire length of the Maranhão state coast are necessary to understand the diversity and distribution of plant species present in the “restings”.

Objective: The objective of this study was to characterize the structure and conservation of the woody vegetation of a “restinga” in Maranhão. **Methods:** Phytosociological sampling of woody vegetation was carried out using the quadrants method, followed by classification of species by successional group; in addition to analyzing the diametric and hypsometric data of the populations whose species presented the highest importance value (IV). **Results:** In total, 24 species and 16 families were identified, 72 % of which were classified in the initial stages of succession. The values of H' and J' were 2.637 nat.ind⁻¹ and 0.830, respectively. The mean height and diameter were 2.1 m and 27.66 cm, respectively. The species *Coccoloba ramosissima* Wedd., *Byrsinima crassifolia* (L.) Kunth, *Anacardium occidentale* L., *Manilkara triflora* (Allemão) Monach, and *Astrocaryum vulgare* Mart. presented the highest IVs. **Conclusions:** It was observed that characteristics such as size, power of regrowth, and ease of regeneration processes could be useful for choosing target species for recovery actions in coastal areas.

Key words: phytosociology; diametric structure; vertical distribution; Maranhão state; environmental restoration.

The restinga has a high environmental relevance in view of the vegetal and physiognomic mosaic, its conservation is essential due to the intense threat caused by anthropic actions (Dias & Soares, 2008). In the Northeast region of Brazil, despite the increase in research for this ecosystem, as in States of the Bahia: Menezes, Santana, Silva, Silva and Araújo (2012), Santos, Zickel and Almeida Jr. (2015); Pernambuco: Almeida Jr., Santos-Filho, Araújo and

Zickel (2011), Cantarelli, Almeida Jr., Santos-Filho and Zickel (2012a); Alagoas: Medeiros, Santos-Filho, Almeida Jr., Pimentel and Zickel (2010); Rio Grande do Norte: Almeida Jr. and Zickel (2012), Medeiros, Almeida Jr., Abreu, Santos-Filho and Zickel (2014); Piauí: Santos-Filho, Almeida Jr. and Zickel (2013a); Paraíba: Vicente, Almeida Jr., Santos-Filho and Zickel (2014); Sergipe: Santana, Rocha, Oliveira, Prata and Ribeiro (2020) - the existing

knowledge about wealth and diversity still does not correspond to the coastal territorial extension of the region. What makes broader analysis impossible due to the particularities in various aspects of its biodiversity and conservation status.

Considering, in particular the Maranhão coastline, the knowledge about restinga vegetation is still restricted to a few floristic studies (Cabral-Freire & Monteiro, 1993; Serra, Lima, & Almeida Jr., 2016; Silva, Araujo, & Almeida Jr., 2016a; Amorim, Amorim, & Almeida Jr., 2016a; Lima & Almeida Jr., 2018) and phytosociological records (Araujo, Silva, & Almeida Jr., 2016; Amorim, Santos-Filho, & Almeida Jr., 2016b; Machado & Almeida Jr., 2019; Almeida Jr., Correia, & Santos-Filho, 2020). These studies represent only a small part of the coast in Maranhão, which is in turn in a large transition area between vegetation in the Amazon and Cerrado domain (Silva et al., 2016b).

Knowing that restingas can serve as a species corridor in ecotonal environments, studies covering the entire length of the Maranhão coast are necessary to understand the diversity and distribution of plant species present in the restingas (Castro, Moro, & Menezes, 2012; Serra, Lima, & Almeida Jr., 2016).

One of the ways to obtain information about plant species for conservation is related to knowledge of the structure of the plant community (Nadkarni, McIntosh, & Cushing, 2008). Thus, height and diameter measurements could provide data on the plant community or be used for the analysis of one or more species of interest in the succession processes. The existence of different strata in the plant community enables greater diversity of micro-habitats, which can increase the diversity of species and ecological interactions (Souza, Souza, Gama, & Leite, 2003). Therefore, vertical stratification could contribute as an indicator of environmental sustainability of a forest, influencing wealth, diversity, and biomass production (Souza et al., 2003) among other factors.

Therefore, evaluation of conditions regarding the dynamics of the forest can generate

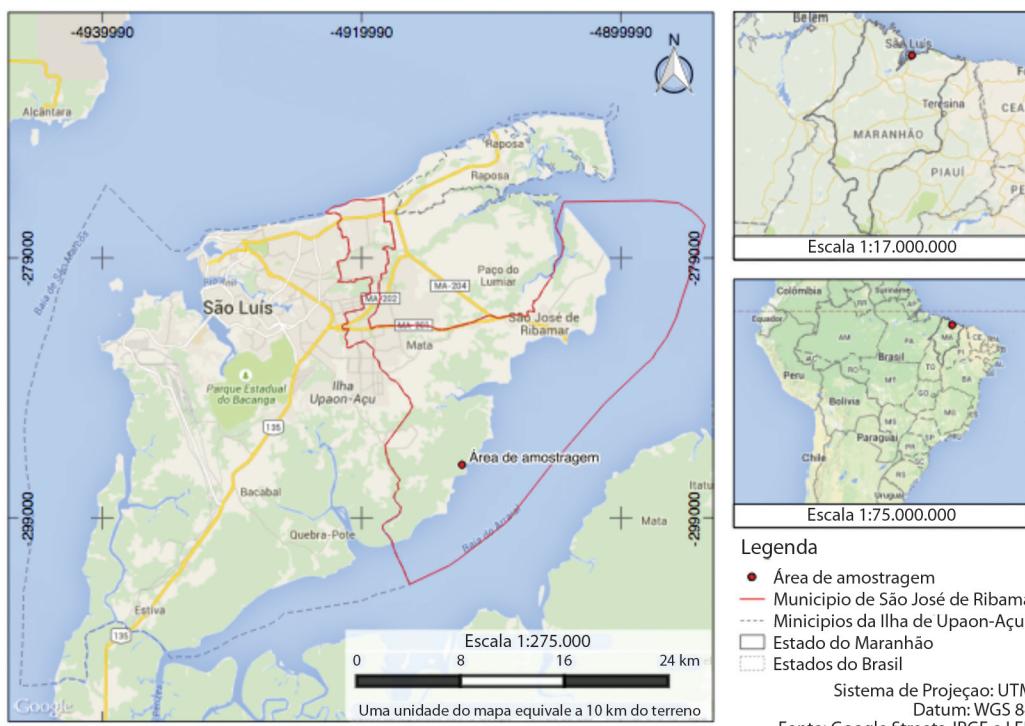

subsidiaries for future forest management actions based on indications about the populations in the development of the plant community (Siminski, Mantovani, dos Reis & Fantini, 2004). Considering the need for data related to the structure of the woody vegetation of the restingas in Maranhão (Serra et al., 2016; Machado & Almeida Jr., 2019; Almeida Jr. et al., 2020), the current study aims to characterize the structure of woody vegetation, analyze the diametric and hypsometric distribution of species of greatest ecological importance, and indicate the level of succession to support future research on recovery and/or management of coastal areas.

MATERIALS AND METHODS

Study area: The collections were carried out in a restinga in the Eastern part of Maranhão Island ($02^{\circ}38'47.85''$ S & $44^{\circ}09'05.76''$ W), on the Sítio Aguahy. The area is owned by Companhia Farmacêutica Quercegen Agronegócios I Ltda., in the municipality of São José de Ribamar, Maranhão state (Fig. 1).

The Sítio Aguahy has an area of 400 ha consisting of a transition between fragments of regenerating Amazon forest, mangrove, and restinga (Serra et al., 2016; Marinho, Muniz, & Azevedo, 2018). The fragment denominated restinga occupies an area of approximately 50 ha, consisting of vegetation from herbaceous to arboreal stratum, presenting physiognomies of floodable fields, non-floodable shrubby, and non-floodable forest (Serra et al., 2016) (Fig. 2). The climate of the region, according to the classification of Köppen (1948), is of the Aw type, having two distinct seasons: a rainy season that extends from January to June and a dry season that begins in July and extends until December. The average rainfall index of Maranhão Island is approximately 2000 mm/year and the average temperatures throughout the year vary between 25.5 and 28.6 °C (INMET, 2016).

Vegetation sampling: Phytosociological sampling was carried out in 2015 and followed

the quadrats method (Cottam & Curtis, 1956). In each quadrant, the individual closest to the central point that meets the inclusion criteria of the sample is marked and identified. Then its distance from the central point of the quadrant is recorded (Durigan, 2003). Five transects were plotted on area, arranged in parallel, each measuring 100 m. Ten points were allocated to each transect, with a distance of 10 m between each point, totaling 50 points. Individuals woody with a diameter at ground height (DGH) ≥ 3 cm were measured. In the case of tillered individuals (plants that had branches at the base of the stem) all the trunks were measured and the sum of the perimeters of each tiller was used to represent the final value of the plant diameter.

This sample size has been considered satisfactory for restinga areas, achieving

sample sufficiency through stability in the species saturation curve (Zickel et al., 2015). In addition, this sampling method follows the studies carried out for the woody strata of the Northeast region (Medeiros et al., 2010; Almeida Jr. & Zickel, 2012; Santos-Filho et al., 2013a; Medeiros et al., 2014; Machado & Almeida Jr., 2019).

For the analysis of the community organization, relative density (RD), relative frequency (RF), basal area (BA), relative dominance (RDO), importance value (IV), Shannon diversity index (H'), Pielou equability index (J'), and total wealth (S) were calculated using the FITOPAC 2.0 package (Shepherd, 2009).

For the analysis of the diametric distribution, a histogram was elaborated with the number of individuals per class of diameter (10 cm interval), representing the plant community. To

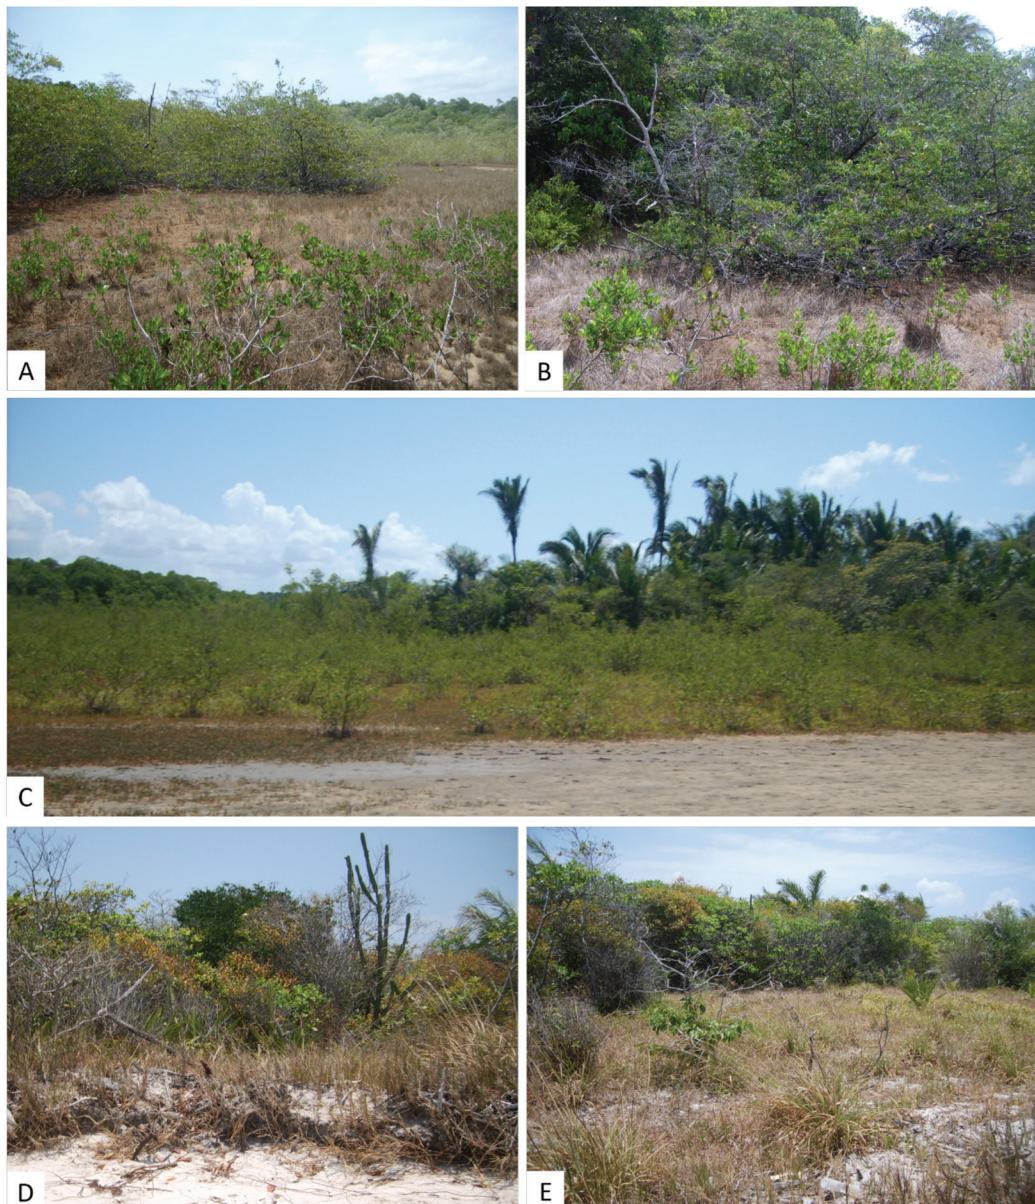

Fig. 2. General aspect of restinga vegetation of Sítio Aguahy is located, municipality of São José de Ribamar, Maranhão state. **A.** and **B.** Physiognomies non-floodable shrubby, **C.** physiognomies non-floodable forest, **D.** and **E.** stretch with herbaceous vegetation in physiognomies non-floodable shrubby. Source E.B. Almeida Jr.

characterize the occupation of vertical space, a histogram was created with the number of individuals per class of height (1 m intervals).

Collection and identification of botanical material: The plants were collected and

processed according to the usual methodology (Peixoto & Maia, 2013). Next, the material was identified through comparison with herbarium material and using specialized literature (Melo, 1996; Rosário, Secco, Amaral, Santos, & Bastos, 2005; Margalho, Rocha, & Secco,

2009; Alexandrino, Sousa, & Bastos, 2011; Menezes, Taylor, Machado, Coelho, & Correia, 2011; Lima & Almeida Jr., 2020; among others). After identification, the exsiccatae were incorporated into the collection of the Herbario MAR, Dep. Of Biology, of the Federal University of Maranhão (UFMA). The list of families followed the APG IV (2016) classification system. Confirmation of the spelling of species and names of authors was carried out by consulting the sites Flora do Brasil (<http://floradobrasil.jbrj.gov.br/>) and Tropicos (<http://www.tropicos.org/>). The classification of species by successional group was carried out through specialized literature according to the criterion suggested by Gandolfi, Leitão and Bezerra (1995).

RESULTS

In total, 24 species were sampled, distributed in 16 families (Table 1). The families with the highest specific wealth were Asteraceae and Rubiaceae (with three species each), and Malpighiaceae, Ochnaceae, and Sapotaceae (with two species each), corresponding to 60 % of the total species sampled (Table 1).

Of the 24 species sampled, the majority (18) were classified as early pioneer and secondary, corresponding to 75 % of the total species. Species characterized as “unclassified” were those that remained indeterminate or identified down to the gender level. These data allow us to infer that the studied community is in an initial succession stage (Table 1).

The species *Coccoloba ramosissima* Wedd., *Byrsonima crassifolia* (L.) Kunth, *Anacardium occidentale* L., *Manilkara triflora* (Allemão) Monach., and *Astrocaryum vulgare* Mart. presented the highest importance values (IV) and the highest number of individuals (Table 1). The total basal area was $1943 \text{ m}^2 \text{ ha}^{-1}$, the value found for the Shannon diversity index (H') was $2.637 \text{ nat.ind}^{-1}$, and for the Pielou equability index (J') was 0.830.

The mean diameter of the species found was 27.66 cm and the maximum 44 cm. The largest number of individuals (82.5 %) was

registered in the first diameter class, corresponding to the intervals from 3 to 13 cm (Fig. 3A). The five species with the greatest IVs were *Coccoloba ramosissima*, *Byrsonima crassifolia*, *Anacardium occidentale*, *Manilkara triflora*, and *Astrocaryum vulgare* with a predominance of young individuals belonging to the first diametric classes.

The mean height found in the shrub-tree component was 2.1 m and the maximum was 6 m. The majority of individuals (97.5 %) were registered between the second and fourth height classes, corresponding to intervals of 1 to 4 m (Fig. 3B). With respect to the species with the highest IVs, there was a predominance of individuals in the range of 1 to 2 m, confirming, together with the diameter, the greater number of young individuals.

Coccoloba ramosissima presented 71.4 % of the individuals in the first classes of diameter (3-18 cm) (Fig. 4A). This species was predominant in the first height class, corresponding to the interval between 1 to 2 m (Fig. 4B). *Byrsonima crassifolia* presented 97 % of individuals in the first two diameter classes (Fig. 4A) and 68.75 % of individuals between the first and second height classes (Fig. 4A).

Anacardium occidentale stood out in the first and second diameter classes (3-13 cm), with a gap in the third diameter class (13-18 cm) (Fig. 4A), whereas the hypsometric distribution (Fig. 4B) did not present any discontinuities. The gap observed may be related to the presence of branches and not to the absence of trees of a certain age. This observation is necessary since the branches are added to give the value of the final diameter of the plant, which contributes to increasing the value related to the caliber of the plant.

The vertical structure was shown to be discontinuous for *Manilkara triflora*, demonstrating regularity in the diametric distribution (Fig. 4A) and presenting gaps in the registration of individuals in the range of 2.5 to 3.5 m (Fig. 4B). The species *Astrocaryum vulgare* presented a diametric (Fig. 4A) and hypsometric (Fig. 4B) distribution with many young individuals and few adult individuals.

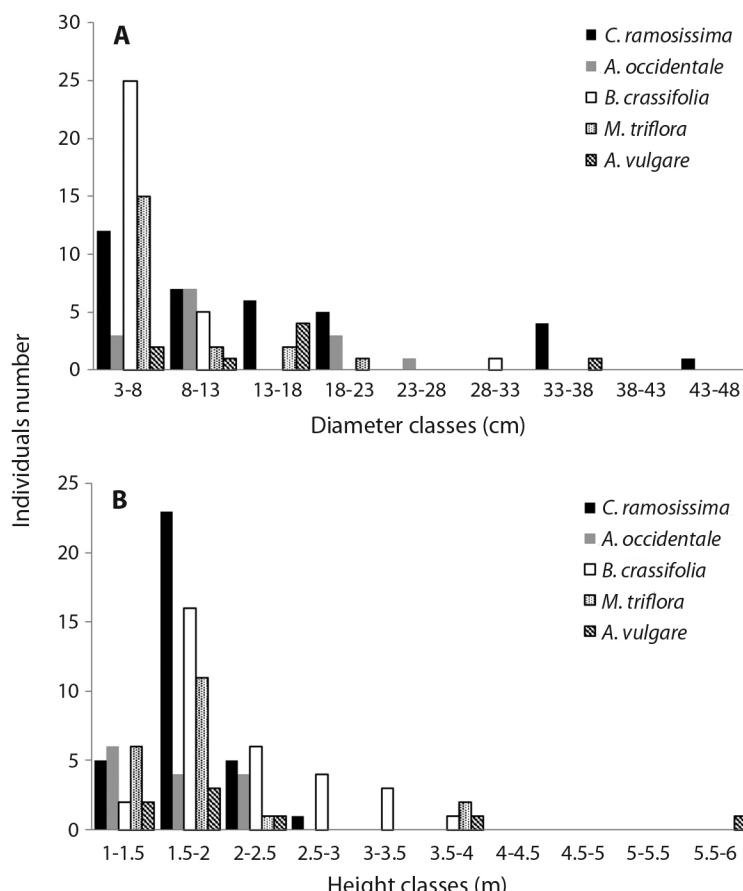

Fig. 4. A. Distribution of individuals by diameter classes (interval of 5 cm); and B. Distribution of individuals by height class (interval of 50 cm), for species of greater IV of the restinga of Sítio Aguahy, São José de Ribamar, Maranhão state, Brazil.

DISCUSSION

The restinga in the present study showed values of diversity and equability (H' of 2.637 nat.ind $^{-1}$ and J' of 0.830) close to the values recorded in the restingas of the Northern coast, such as Ceará, Piauí, and Maranhão (Castro et al., 2012; Santos-Filho et al., 2013a; Machado & Almeida Jr., 2019; Almeida Jr. et al., 2020). This fact may indicate that the species present more heterogeneous distribution due to the environmental peculiarities of each restinga, such as nutrient availability, acidity content, physical-chemical composition of the soil, and periodic flooding (Santos-Filho et al., 2013a).

Based on floristic data, Serra et al., (2016) highlighted the similarity between the restinga of the present study with the restingas of Pará, suggesting that Amazonian species contribute to the colonization of the Eastern coast of Maranhão, thus being able to direct new studies to expand knowledge on the areas of Amazonian vegetation in Maranhão.

The species found in the present study are widely distributed throughout the Brazilian territory, being found in different ecosystems, and not characterized as endemic to restinga areas (BFG, 2015). Despite this, restinga areas require attention due to their fragility faced with human actions, as deforestation and the consequent removal of superficial layers of soil interfere in the successional process of these areas, leading to possible losses in the diversity of species and ecological interactions. This demonstrates the need for conservation actions in the areas, since the restinga can serve as an ecological corridor for ecotonal areas (Castro et al., 2012; Serra et al., 2016).

The high number of individuals in the first diameter class together with the high density of species belonging to initial successional groups indicate that this area is in the process of regeneration, as had already been reported by Serra et al., (2016).

The horizontal distribution of study area had higher mean diameters in relation to other areas of restinga of the Northeast coast (Santos-Filho et al., 2013a; Machado & Almeida

Jr., 2019; Almeida Jr. et al., 2020). This fact may be related to the significant number of branches, as observed in individuals of *Anacardium occidentale*, which naturally have many branches in restinga areas (Almeida Jr. Et al., 2011; Machado & Almeida Jr., 2019; Almeida Jr., Correia, & Santos-Filho, 2020). The branches of *Coccoloba ramosissima* may be associated with the regrowth ability and could be considered an important mechanism in the processes of recolonization in degraded areas. This may play an important role in forest restoration during the initial successional stages, since as climatic species are established, this process becomes rarer in the plant community (Mariano, Junior, Silva, & Amorim, 2007; Chazdon, 2008).

The development of branches in species in restingas contributes positively to the establishment and growth of these plants (Sá, 2002). In this way, the diametric values, considering the sum of the branches, generate a large caliber, allowing these species to occupy more space, and so to compete and stand out in the woody stratum.

As for the size of the vegetation, it can be considered that in the restinga of the present study there was a greater predominance of shrubs and trees of low height, similar to the plants of restingas on the coast of the Piauí state (Santos-Filho et al., 2013a). The composition woody community from restinga of Curupu (Machado & Almeida Jr., 2019) and from restinga of Alcântara (Almeida Jr. et al., 2020) in Maranhão state, and the restinga of Pecém, in Ceará state (Castro et al., 2012), it was taller, with a variation of 4 to 4.4 m in the average height of the individuals, in relation to the vegetation of the present study. This difference is probably due to the different physiognomies of restingas (Santos-Filho, Almeida Jr., Soares, & Zickel, 2010) and by the diversity of species in each area. Furthermore, the area under study presents ecotonal vegetation, consisting mainly for species of the Amazonic biome and Cerrado biome (Serra et al., 2016; Machado & Almeida Jr., 2019; Almeida Jr. et al., 2020), reinforcing the particularity regarding the structure

of the woody vegetation of the restingas in Maranhão state.

Byrsonima crassifolia, registered along the restinga areas of the Northeast (Castro et al., 2012), is highlighted in the area by the expressive number of individuals. This species is important in the ecological relations of this restinga, such as for the pollination and construction of nests of pollinators (Mendes & Rêgo, 2007).

Zickel et al. (2015) pointed out that *Anacardium occidentale* occurs in several restinga areas on the Northeast coast (Sacramento, Zickel, & Almeida Jr., 2007; Cantarelli, Almeida Jr., Santos-Filho, & Zickel, 2012b; Santos-Filho et al., 2013a), with the presence of branches being common. However, the predominance of this species in some restingas may be associated with the degree of degradation of the area or the economic interest, due to the commercial value of the fruits (the cashew) (Zickel et al., 2015).

With respect to the diametric and hypsometric distribution of *Manilkara triflora*, the presence of individuals that developed horizontally through branches, but did not grow vertically was noticed. This behavior can be explained by the characteristics of the soil, which can hinder the growth of the plant in stature (Passioura, 2002), or by the stressful conditions of the area, such as high soil salinity, in addition to the shallow soil, which tend to favor strategies such as growth and reproduction of the individual through branches (Sá, 2002; Fonseca, Ribeiro, & Carvalho, 2013). This species, together with *Manilkara bidentata*, found in the study area, are Amazonian species and of economic interest. Although these species are not listed as endangered as a result of their wide distribution, they require attention due to the loss of habitat and exploitation for the use of wood in Maranhão, which could lead to a change in the conservation status of these species in a short time, which may compromise the community and structural arrangement of woody vegetation, especially in coastal areas which are the first to experience suppressed vegetation (Almeida Jr., Santos Filho, & Zickel, 2012).

The gap observed in the height and diameter classes of *Astrocaryum vulgare* may suggest that a factor is hindering the establishment of adult individuals in the area or that a disturbance may have prevented the development of individuals. This species also stands out as it is an arborescent palm, capable of establishing quickly in disturbed environments with lots of light (Santos-Filho, Almeida Jr., & Soares, 2013b). In addition to being important in the processes of regeneration and ecological succession, this species has the ability to recruit and rapidly modify the environment (Santos-Filho et al., 2013b).

It is known that lists on floras and plant structures can be consulted to choose the species to be used in recovery actions (Ferreira et al., 2013). In habitats subjected to extreme environmental pressures, such as restinga areas, the most abundant species seem to provide adequate environmental conditions for the germination and growth of other species (Scarano, 2002).

The present study highlighted that regarding the succession level the vegetation presented characteristics of being in an initial stage, with respect to factors such as size and regrowth power. This could be important in regeneration processes, such as in recovery actions in other coastal areas or similar environmental conditions. The study also made it possible to highlight the use of species with the highest IV for maintenance and recovery in relation to species diversity and ecological interactions found in restingas. Finally, it is worth noting that "restinga" areas are among the most impacted ecosystems in Brazil, meaning studies on the conservation status of these environments are of great importance.

RESUMEN

Fitosociología, nivel sucesional y conservación del componente leñoso de una “restinga” en isla Maranhão, Brasil

Introducción: Las “restingas” pueden servir como corredor de especies en ambientes ecotónicos debido a los aspectos de la composición de la flora. Los estudios a lo largo de la costa del estado de Maranhão son necesarios para comprender la diversidad y distribución de las especies de plantas presentes en las “restingas”. **Objetivo:** El objetivo de este estudio fue caracterizar la estructura y conservación de la vegetación leñosa de una “restinga” en Maranhão. **Métodos:** Se realizó un muestreo fitosociológico de la vegetación leñosa utilizando cuadrantes, seguido de la clasificación de especies por grupo sucesional; además de analizar los datos diamétricos e hipsométricos de las poblaciones cuyas especies presentaron el de mayor valor importancia (VI). **Resultados:** En total, se identificaron 24 especies y 16 familias, 72 % de los cuales fueron clasificados en las etapas iniciales de sucesión. Los valores de H' y J' fueron 2.637 nat.ind⁻¹ y 0.830, respectivamente. La altura y el diámetro medios fueron de 2.1 my 27.66 cm, respectivamente. Las especies *Coccoloba ramosissima* Wedd., *Byrsonima crassifolia* (L.) Kunth, *Anacardium occidentale* L., *Manilkara triflora* (Allemão) Monach, y *Astrocaryum vulgare* Mart. presentaron los valores de mayor importancia (VI). **Conclusiones:** se observó que

características como el tamaño, capacidad de rebrote y la facilidad de los procesos de regeneración podrían ser útiles para elegir las especies objetivo para las acciones de recuperación en las zonas costeras.

Palabras clave: fitosociología; estructura diamétrica; distribución vertical; estado de Maranhão; restauración ambiental.
