**Abstract:** We rated some reproductive characteristics of white shrimp *Litopenaeus vannamei* (Boone, 1931) males using 46 farmed individuals (weighing 21.42±0.56 g) and 40 wild individuals (weighing 36.10±0.72 g). In farmed shrimps, spermatophore mean weight was 8.94±0.51 mg; total mean sperm count was 3.90±0.27 x 10<sup>6</sup> in each spermatophore; and mean percentage of normal sperm was 86.9±0.37 %. In wild individuals, the respective values were 30.68±2.32 mg; 6.22±1.09 x 10<sup>6</sup>; and 62.1±3.56 %. In both groups, the differences between right and left spermatophore were not significant (p<0.01). There were significant differences in spermatophore weight and percentage of normal sperm between farmed and wild shrimps; sperm counts differences, however, were not significant (p<0.01). The relationship between spermatophore weight (Ws) and individual weight (Wo) was Ws (mg)=1.23 (Wo)-17.34 (r<sup>2</sup>=0.89), in farmed shrimps; and Ws (mg)=2.57 (Wo)-60.04 (r<sup>2</sup>=0.64), in wild ones. In cultivated organisms, the relationship between sperm counts (Cs) and individual weight (Wo) was Cs (x 10<sup>6</sup>)=1.13\*10<sup>-4</sup>\* (Wo) 3.361 (r<sup>2</sup>= 0.85); and versus spermatophores weight was Cs (x 10<sup>6</sup>)=0.439\* (Ws) 0.984 (r<sup>2</sup>= 0.90). In wild organisms, there was no correlation. The proportion of normal sperm ranged from 79.8 to 95.2 % (86.9±0.37 %) and from 14.0 to 91.5 % (62.1±2.52 %), in farmed and wild shrimps, respectively. The most frequent abnormalities in both farm and wild animals were sperm without spike (49.3 % and 76.6 %, respectively) and irregular shape (35.8 % and 17.7 %). The less frequent occurrences were those of bent (10.2 % and 4.29 %) and double spike (4.7 % and 1.41 %). Rev. Biol. Trop. 55 (1): 199-206. Epub 2007 March. 31.

**Key words:** *Litopenaeus vannamei*, reproduction, males.

The stocking of postlarvae for penaeid shrimp farming has passed through different stages from their collection in the wild to the capture of impregnated females for further spawning and rearing of larvae, up to the artificial manipulation of maturation of females, mating, spawning and rearing of larvae in laboratory facilities. In fact, the difficulty of closing the life cycle in the laboratory has been one of major obstacles for the establishment of shrimp culture as an industry (Chamberlain and Gervais 1984).

In the shrimp farming industry the control of reproduction in captivity is a critical factor

for the success because this would guarantee the supply of postlarvae of a known species to be stocked and grown (Bray and Lawrence 1992). The development of techniques to induce maturation and reproduction in penaeid shrimps has been focused mainly on females, in spite of the fact that reproductive problems of males have been, in some instances, responsible for some of the reproduction failures in captivity of many penaeid species (Leung-Trujillo and Lawrence 1987). In Mexico, until a few years back, the main source for the initiation and renewal of breeding stock in maturation facilities was the feral population; however, because

of the risks this group represents (potential carrying of virus and other diseases), as of late, the search for more reliable sources of breeding stock has become a necessity and the best alternative have been organism coming from culture facilities.

The objective of this work is to assess comparatively the reproductive potential of farmed and wild males of *Litopenaeus vannamei* to determine whether the former could also be used as breeding stock.

## MATERIALS AND METHODS

A total of 86 organisms were utilized, 46 of which were collected from grow-out ponds of a farm in southern Sinaloa, Mexico. Their weight ranged from 15.44 to 28.47 g (mean=21.42±0.56). The remaining 40 individuals ranging from 28.15 to 45.56 g (mean=36.10±0.72 g), wet weight, were collected at sea on the southern Sinaloa continental shelf on board the 50 m long research vessel (B/O) "EL PUMA" by means of a commercial otter trawl-type net of 75 feet, off the mouths of the Presidio and Baluarte rivers, trawled at an average depth of 20 m. The organisms were placed in circular plastic tanks of 0.50 m in diameter, in a room with controlled temperature (ca. 28 °C), at a salinity nearing that of the sea (around 34 ppt) and a photoperiod regime of 12:12 h. (light: darkness). A fresh-frozen diet consisting of a mixture of squid (*Loliguncula* sp. and *Loliolopsis* sp.) and small shrimps (*Xiphopenaeus* sp. and *Rimapenaeus* spp.); at a 1:1 ratio was supplied in a 15 % proportion of the wet weight per day, distributed in two rations supplied at 09:00 and 17:00 h. In both, the remains of food and wastes were removed. Water exchange rate was maintained at 150 % per day.

The parameters measured were: a) spermatophore weight; b) sperm count; and c) percentage of normal sperm. Spermatophores were ejected manually, applying a light pressure at the basis of the fifth pair of pereopods on the side of the targeted organ to be ejected.

Spermatophore wet weight was measured, after excess water was removed, on an analytical balance to the nearest 0.005 mg. Subsequently, spermatophores were homogenized in a glass tissue grinder in 3.0 ml of filtered and UV-sterilized seawater or in artificial seawater, prepared after Leung-Trujillo and Lawrence (1987).

Sperm counts were estimated from the average count of three samples of 0.0001 ml each contained within an American Optical haemocytometer, using a microscope with a 40x objective. The percentage of normal sperm was determined by direct observation of the samples in the haemocytometer counting the number of normal sperm (spherical body and straight and elongate spike) and the number of abnormal sperm (irregular form and bent, double, or missing spike) (Talbot *et al.* 1989).

Data of farmed and feral specimens weight, right and left spermatophores weight, sperm count and the percentage of normal sperm were statistically compared using a *t*-test for independent samples (Zar 1980); and with a modified *t*-test for unequal variances (Ott 1984). Sperm counts and percentage of normal sperm data were modified to make the variance independent of the mean, by taking the square root of  $X + 3/8$  (Bray *et al.* 1985) and arcsine transformation (Leung-Trujillo and Lawrence 1985), respectively. The mean values are presented as Mean ± standard error of the mean (SEM).

## RESULTS

Tables 1 and 2 summarize pooled data of size, right and left spermatophores weight, sperm count and percentage of normal sperm of farmed and wild shrimps. Spermatophore weight of farmed shrimps ranged from 1.7 to 19.5 mg (8.94±0.51 mg); and that of wild shrimps from 9.7 to 80.3 mg (30.68±2.32 mg). In both, the differences among right and left spermatophores were not significant ( $t=0.015 < t_{0.01(2)90}=2.632$ ; and  $t=0.046 < t_{0.01(2)78}=2.640$ ). The spermatophore weight/shrimp weight ratio ranged from 0.010 to 0.068 %

TABLE 1

Comparison of right and left spermatophores weight (Ws), spermatophore weight/organisms weight ratio (Ws/Wo), sperm count and percentage of normal sperm of the farmed and wild *Litopenaeus vannamei*

Parameter	Farmed		Wild	
	Right	Left	Right	Left

Sperm count (x 10 <sup>6</sup> )	3.90 <sup>a</sup> ± 0.27	6.22 <sup>b</sup> ± 1.09
Normal sperm (%)	86.85 <sup>a</sup> ± 0.37	62.12 <sup>b</sup> ± 2.52
N	92	80

Means with equal super index are not statistically different (p<0.01).

(0.039±0.001 %), in farmed shrimps; and from 0.034 to 0.183 % (0.082±0.002 %), in wild shrimps. In the latter, the difference was statistically significant ( $t=11.735 > t_{0.01(2)147}=2.610$ ), as well as for spermatophore weight among farmed and wild shrimps ( $t=12.714 > t_{0.01(2)95}=2.629$ ). In farmed shrimps, sperm count in each spermatophore ranged from 0.85 x 10<sup>6</sup> to 11.54 x 10<sup>6</sup> (3.90±0.27 x 10<sup>6</sup>); while that in wild shrimps ranged from 0.05 x 10<sup>6</sup> to 29.31 x 10<sup>6</sup> (6.22±1.09 x 10<sup>6</sup>), however, in spite of the apparent differences between the

two groups, there were no significant differences in sperm counts between right and left spermatophores ( $t=0.021 < t_{0.01(2)90}=2.632$ ; and  $t=0.036 < t_{0.01(2)78}=2.640$ ), nor in the sperm counts among farmed and wild shrimps ( $t=1.809 < t_{0.01(2)111}=2.621$ ).

Spermatophore weight (Ws) increases in relation to the organism weight (Wo) increase (Fig. 1A and 1B). The relationships of both, farm and wild shrimps are defined by the following regression equations:

$$Ws \text{ (mg)} = 1.23 \text{ (Wo)} - 17.34; (r^2=0.89, p<0.05);$$

$$Ws \text{ (mg)} = 2.57 \text{ (Wo)} - 60.04; (r^2=0.64, p<0.05);$$

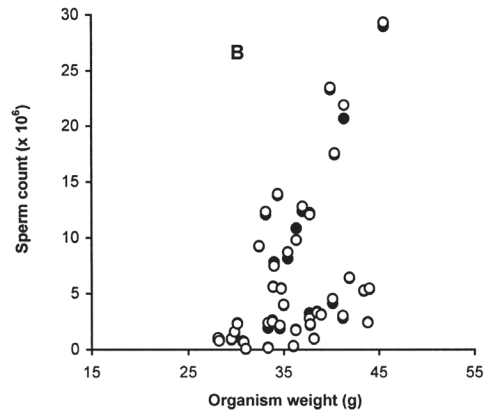

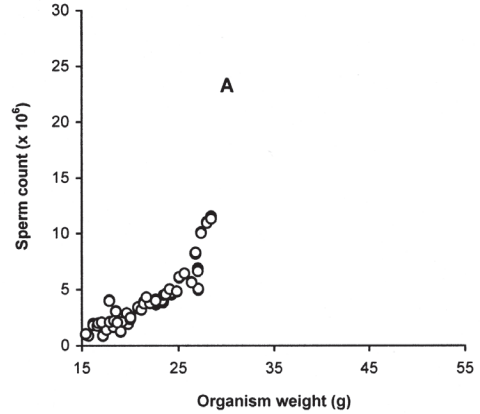

for farmed and wild shrimps, respectively; both were significant.

Similarly, sperm counts (Cs) in farmed shrimps increase in relation to increases of organism weight (Wo) (Fig. 2A) and spermatophore weight (Ws) (Fig. 3A). In both cases, a positive significant correlation was observed and the relationships are defined by the following regression equations:

$$Cs(x \ 10^6) = 1.13 \cdot 10^{-4} \cdot (Wo) + 3.361; (r^2=0.85, p<0.05);$$

and

$$Cs(x \ 10^6) = 0.439 \cdot (Ws) + 0.984; (r^2=0.90, p<0.05).$$

● Left ○ Right

Fig. 1. Relationship between spermatophore weight and individual weight in farmed (A) and wild (B) *Litopenaeus vannamei*.

In wild shrimps, on the other hand, sperm count in relation to organism and spermatophore weights, was exceedingly variable. For example, in shrimps weighting 38 and 40 g with spermatophores of 28.5 and 39.5 mg, the sperm counts were  $23.46 \times 10^6$  and  $0.96 \times 10^6$ , respectively. Therefore there was no correlation between these parameters in those males (Fig. 2B and 3B).

In farmed shrimps, the proportion of normal sperm ranged from 79.8 to 95.2 % ( $86.85 \pm 0.37$  %); while that in wild shrimps

Fig. 2. Relationship between sperm counts and individual weight in farmed (A) and wild (B) *Litopenaeus vannamei*.

ranged from 14.0 to 91.5 % ( $62.12 \pm 2.52$  %). In both, the differences in the percentage of normal sperm between right and left spermatophores were not significant ( $t=0.234 < t_{0.01(2)90}=2.632$ ; and  $t=0.150 < t_{0.01(2)78}=2.640$ ), but the differences in percentage of normal sperm between farmed and wild shrimps were significant ( $t=10.147 > t_{0.01(2)86}=2.634$ ).

Among farmed shrimps, 69 of the 92 spermatophores presented 80 to 90 % of normal sperm; 14 more than 90 % and 9 had between 70 and 80 %. In feral shrimps, only 24 of the 80 spermatophores presented a percentage of normal sperm between 80 and 90 %; 17 between

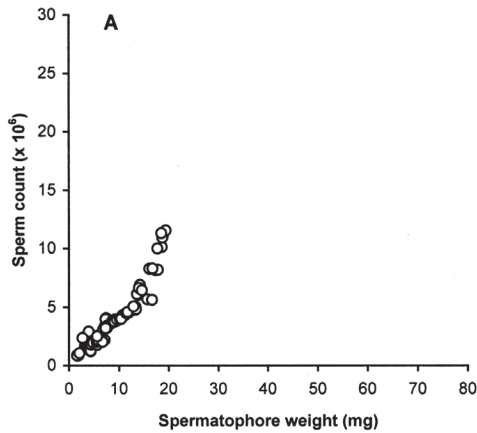

Fig. 3. Relationship between sperm counts and spermatophores weight of farmed (A) and wild (B) *Litopenaeus vannamei*.

70 and 80 %; 5 between 10 and 20 %; and in only two of the cases the proportion was higher than 90 % (Fig. 4A).

Of the four types of abnormal sperm, in both farmed and wild shrimps, the most frequent were: missing spike (Ms; 49.3 and 76.6 %, respectively) and irregular form (If; 35.8 and 17.7 %, likewise). Less frequent were those with bent (Bs; 10.2 and 4.3 %) and double spike (Ds; 4.7 and 1.4 %) (Fig. 4B).

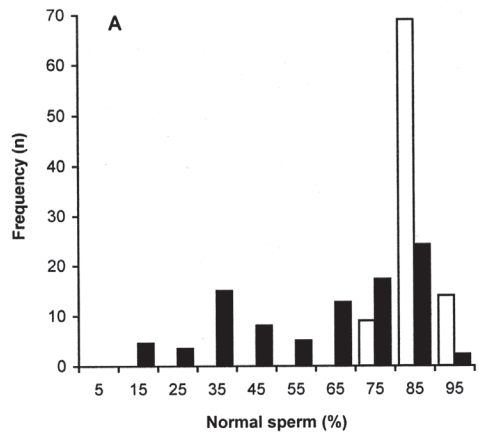

Fig. 4. Frequency of normal sperm (A) and of abnormal sperm types (B) observed in farmed and wild *Litopenaeus vannamei* (Ms: missing spike; If: irregular form; Bs: bent spike; Ds: double spike).

## DISCUSSION

In ponds, the presence of adult shrimp (joined petasma) of less than 20 g in weight is common. Although the maturation of males in penaeid shrimps does not require special environmental or nutritional conditions, is not very clear as yet, if such maturation is related to size or age. *L. vannamei* males, 6.5 months old, of 12.51 g, present well developed spermatophores

(Ogle 1992). On the other hand, in the marine environment, shrimps of the same species, weighting more than 20 g, are still sexually immature. The minimum weight of sexually mature shrimp males of this species is 21.13 g (Calderon-Perez *et al.*, unpubl.).

In farmed shrimps of size between 15 and 30 g, the values of spermatophore weight (1.7 to 19.5 mg), sperm counts ( $0.85 \times 10^6$  to  $11.54 \times 10^6$ ) and percentage of normal sperm (79.8 to 95.2 %), were proportionally higher than those found elsewhere. Leung-Trujillo and Lawrence (1985) reported similar values although in males bigger than 30 g while Alfaro and Lozano (1993) reported much lower sperm counts and percentage of normal sperm in shrimps of size between 22 to 25 g.

The considerably high values of the correlation coefficients between organism and spermatophore weight ( $r^2=0.89$ ), and between spermatophore weight and sperm count ( $r^2=0.85$ ), and of the percentage of normal sperm (79.8 to 95.2 %) appears to indicate that these organisms were in a stage of first maturity and therefore the spermatophores would have been recently deposited in the terminal ampoules of the males. In this regard, Alfaro and Lozano (1993) observed a deterioration of the spermatophores of *P. vannamei* within a period of two to three months, in farm ponds. It also suggests that such deterioration is a normal occurrence in the reproduction process of penaeid shrimps. Feral shrimps on the other hand, although bigger (28 to 46 g), and with higher spermatophore weight range (9.7 to 80.3 mg), did not show proportional higher values in the reproduction parameters examined as it would be expected, i.e., sperm count ( $0.05 \times 10^6$  to  $29.31 \times 10^6$ ) and percentage of normal sperm were extremely variable (14 to 91.5 %).

The former is probably due to the aforementioned deterioration of the spermatophores, which is manifested as the high variability of sperm count and percentage of normal sperm. The low but acceptable correlation coefficient observed between organism weight and spermatophore weight ( $r^2=0.64$ ) and the lack of correlation between the organism weight and

the spermatophore weight with sperm counts and the low percentage of normal sperm seem to strengthen this argument with regards to the amount and quality of the sperm. What the above actually means is that the presence of spermatophore of good size and appearance does not always guarantee good sperm counts and adequate percentage of normal sperm.

According to Leung-Trujillo and Lawrence (1987) the deterioration of spermatophores in captive *P. setiferus* is a predictable event, and to Talbot *et al.* (1989), the bacterial infection is not the primary cause of this problem. Alfaro (1990), Gomes and Primavera (1993) pointed out that the reproductive performance of many species of crustacean is affected by the water quality and the stress conditions.

The results of the evaluation of the spermatophore of wild shrimps indicates that their deterioration is a natural process. In this regard, Alfaro and Lozano (1993) suggest that such deterioration is a natural way of getting rid of old spermatophores. Leung-Trujillo and Lawrence (1985) found that young specimens of *P. vannamei* have early and small spermatophores. In this study, the spermatophore weight of farmed shrimps represented, in average, 0.039 % of the organism weight, about half of that observed in wild shrimps (0.085 %).

In relation to sperm quality, Motoh (1981), Leung-Trujillo and Lawrence (1985) and Alfaro (1993) coincide that in penaeid shrimps the highest percentages of abnormal sperm occur in young organisms; however, in this work, the higher percentages of abnormal sperm (86.0 %) were observed in wild, bigger and presumable older shrimps while in farmed shrimps of approximately five to six months of age, that percentage was relatively low (20.2 %). This is also attributed to the above mentioned process of deterioration.

Among the sperm abnormalities, the highest percentages were those of the body without spike, in both farmed (49.3 %) and wild shrimps (76.6 %). The latter is similar to the 77 % observed by Leung-Trujillo and Lawrence (1985). It would appear that this type of abnormality is also the most frequent in *P. monodon*

since Pratoomchat *et al.* (1993) found more than 95 % of sperm without spike out of the totality of abnormal sperm.

The importance of the appearance lies in the fact that abnormal or deformed spermatozoa do not have the same capability for ovule fertilization as normal or non-deformed spermatozoa have (Motoh 1981). The spermatozoa spike in rock shrimp *Sicyonia ingentis* seems to be required for the orientation of the sperm and subsequent penetration in the ovule (Clark *et al.* 1981).

In conclusion, the weight of the organisms and the weight of the spermatophore were significantly higher in feral than in farmed male shrimps; however, even though spermatozoid counts were also higher in wild than in farmed specimens ( $6.22 \pm 1.09$  and  $3.90 \pm 0.27$  million) the difference was not significant.

The percentage of normal spermatozoids was significantly higher in farmed than in feral males.

The last item lead us to suggest that in spite of the higher proportion in spermatophore weight and spermatozoid count of feral males, the higher percentage of normal spermatozoids in farmed shrimps compensates such inequalities, making farmed males a more reliable source of spermatozoids for female fertilization given their availability and consistency. This would be particularly important in laboratories where artificial insemination is practiced.

#### ACKNOWLEDGMENTS

Thanks are due to the technical staff of the Parque Camaronicola of the Federación de Cooperativas "Guerreros del Sur", to the Fisheries Biologists Jesus Peiro L. and Enrique Lopez B., for the donation of the organisms; to the crew and Captain of the B/O "El Puma", for their support in the collection of shrimp at sea; and to Hugo A. López C., Jorge G. Gaona M. and Edna E. Aguilar Abrego, for their collaboration.

#### RESUMEN

Se evaluaron características reproductivas como peso del espermatóforo, número de espermatozoides y porcentaje de espermatozoides normales en 86 organismos de camarón blanco (*Litopenaeus vannamei*). De éstos, 46 individuos provinieron de estanques de cultivo con un peso de  $21.42 \pm 0.56$  g y el resto, 40, silvestres con un peso de  $36.10 \pm 0.72$  g. En los camarones cultivados, el peso de los espermatóforos fue de  $8.94 \pm 0.51$  mg; el número total de espermatozoides en cada espermatóforo fue de  $3.90 \pm 0.27 \times 10^6$ ; y el porcentaje de espermatozoides normales fue de  $86.9 \pm 0.37$  %. En los silvestres, los valores respectivos fueron de  $30.68 \pm 2.32$  mg;  $6.22 \pm 1.09 \times 10^6$ ; y  $62.1 \pm 3.56$  %. En ambos grupos, las diferencias entre los espermatóforos derecho e izquierdo no fueron estadísticamente diferentes ( $p < 0.01$ ). Las diferencias en el peso de los espermatóforos y el porcentaje de espermatozoides normales, entre los camarones cultivados y silvestres, fueron significativas ( $p < 0.01$ ); sin embargo, en el número de espermatozoides tales diferencias no fueron significativas ( $p < 0.01$ ). La relación entre el peso del espermatóforo ( $W_s$ ) y el peso de los individuos ( $W_o$ ) fue  $W_s \text{ (mg)} = 1.23(W_o) - 17.34$  ( $r^2 = 0.89$ ), en camarones cultivados; y  $W_s \text{ (mg)} = 2.57(W_o) - 60.04$  ( $r^2 = 0.64$ ), en los silvestres. En organismos cultivados, la relación entre el número de espermatozoides ( $C_s$ ) y el peso de los individuos ( $W_o$ ) fue  $C_s (*10^6) = 1.13 * 10^{-4} * (W_o) + 3.361$  ( $r^2 = 0.85$ ); y entre el peso de los espermatóforos fue  $C_s (*10^6) = 0.439 * (W_s) + 0.984$  ( $r^2 = 0.90$ ). En el caso de los organismos silvestres, no hubo correlación. La proporción de esperma normal varió de 79.8 a 95.2 % ( $86.9 \pm 0.37$  %) y de 14.0 a 91.5 % ( $62.1 \pm 2.52$  %), en camarones cultivados y silvestres, respectivamente. Las anomalías más frecuentes tanto en los cultivados como en los silvestres fueron esperma sin spike (49.3 % y 76.6 %, respectivamente) y los de forma irregular (35.8 % y 17.7 %). Las presencias menos frecuentes fueron las de spike torcido (10.2 % y 4.29 %) y doble (4.7 % y 1.41 %).
